The object of this thesis is to bring before the minds of its readers the design, installation and operation of a modern automatic electric signalling system for a steam railroad.

An exact copy of the specifications governing material and construction is included. The descriptions of materials and mechanisms are supplemented, as far as possible, by lettered prints and diagrams, in an effort to bring out every detail which will make the construction and operation more clearly understood.

In taking up the electrical circuits and connections in detail, the sole purpose is to impress their great importance upon the minds of the readers, and to show their connection with the terms of the specifications.

The work of installing the system herein described is at the time of this writing in progress, and it is hoped that this paper may arouse the interest of the technical students and others who may chance to read it.
along signal lines, at least to the extent of visiting this installation and observing the system in actual operation.

June 4th, 1908.
The Automatic Electric Signal, as used on steam railroads, is one which has for its operating power, electricity, directly under control of the train on the rails. This is accomplished by dividing the track into sections insulated from each other by special insulating rail joints which replace the ordinary fish plates. At one end of each section is placed a battery, the positive side being connected to one rail and the negative side to the other rail. At the other end of this section is placed a magnetic switch or relay, the terminals of its magnetizing coil being connected to the rails. The armature of this relay carries contact points which close when the armature is attracted to the core and open when the magnetizing force is cut off or considerably reduced. These contact points control the current which operates the electrically driven mechanism governing the signal movement.

To insure safety in operation, all signal positions other than those meaning danger, are obtained by the operation of a motor against the force of gravity. The signal arm or blade is also held in these positions by a current in a closed circuit. Any failure or break in this circuit releases the holding mechanism, and the
signal arm or blade returns to the danger position by the force of gravity and remains there until the fault is remedied. These are the fundamental principles on which all automatic signals are operated. There are many appliances operated in conjunction with automatic signals, but these will be taken up in detail in the following pages.
The Automatic Signal System, described in the following pages, is being installed by the Continental Signal Company of Chicago, on the double track main line of the Chicago & Western Indiana Railroad. It extends a distance of ten miles, and embraces nearly all of the complications usually encountered in an installation of this kind. It is carried through six interlocking plants; one drawbridge; across two trolley line crossings; and into an interlocking plant at either end.

The following is a copy of the specifications as submitted by the railroad company:

**AUTOMATIC BLOCK SIGNALS:**

To govern main and double tracks between Hammond Junction and State Line, as shown by diagram dated July 26, 1907, which contemplates the use of thirty-five (35) automatic block signals and embraces the interlocking plants at State Street, crossing of C...T., passenger and freight tracks; Turnpike, crossing Illinois Central Railroad; 1-2 St. Street, junction South Chicago Branch; C...T. Train line, swing bridge; Burnham, crossing South Chicago Southern; State line, railroad crossing and Pullman Junction, junction of C...T. passenger and freight tracks.

The block signals are to be one arm, three position, automatic electric, of the manufacturer's latest pattern, indication as follows: Arm in horizontal position, to show red at night, block ahead occupied; arm at an angle of forty-five (45) degrees to the horizontal, to show green at night, block ahead clear but second block ahead occupied; arm in vertical position, to show white at night, both first and second blocks clear.
The top arm on the home signal shall be semi-automatic electric. Indication given will be the same as at the block signals, except that they shall be controlled by the levers in the interlocking machine.

The circuits shall be arranged so that the signal will be returned to the normal position automatically, and it shall not again become operative until the train has passed the first block signal beyond the crossing and the levers in the tower have been returned to normal and then reversed.

The normal position for the automatic block signal shall be at clear, and, for the semi-automatic signals, shall be at stop position.

The apparatus must be so arranged that, if any appliances used in any way in connection with the signals shall become out of order, the signal affected shall immediately assume and remain in the stop position. This is also to apply to indicators.

Two arm signals shall be used for all home signals. There is no diverging route, the lower arm shall be fixed for stop position. Where there is a diverging route, the lower arm is not to be semi-automatic.

At State Line, Cheinham and 11th Street interlocking plants, the lower arm on home signals are wire connected.

At State Street and Fullman Junction, the lower arm is wire-connected.

Suitable concrete foundations shall be built. Top of foundations to be level with top of rail. Having four (4) one-inch anchor bolts 32' long, properly built in.

The trunking shall be imbedded in the concrete, to permit wires to be run in signal case.

Storage batteries, 5 D Chloride Accumulator or its equivalent, shall be provided of sufficient capacity to operate the signals, signal circuit, switch...
indicators and tower indicators.

Not less than six cells shall be used in one battery, to operate signal. Where two signals are directly opposite each other, both signals are to be operated from one battery.

Gravity batteries shall be used for all track circuits and for charging the storage batteries. At least three cells of gravity batteries must be used to charge one storage cell.

Circular watertight concrete battery wells shall be provided of approved design; size, 5' x 7' inside measurements. Suitable battery shelving must be provided, and framed so that the nails and screws do not carry the weight of the batteries.

The cover for hatchway must be lined with #1 Galvanized Iron, painted. Provision must be made for locking same. Wires run in battery wells must be carried on suitable wooden or porcelain cleats.

There track batteries can not be put in battery well, cast iron battery chute must be provided.

Chute must be not less than 6' deep, and provided with elevator to hold three cells of 6" x 3" gravity batteries.

Track relays are to be enclosed type and are not to have less than three (3) points, three (3) front and two (2) back contacts, four (4) ohm resistance. Line relays are not to have more than three (3) points, three (3) front and two (2) back contacts, thousand (1000) ohm resistance.

Relays to be of the enclosed type. Wherever possible, relays are to be placed in signal cases; otherwise, cast iron relay boxes with iron tie post, designed to be bolted to the top of a concrete foundation, must be provided.
**Bonding:**

The bond wires, No. 6 E.D.S. Galvanized, 52" in length, must be used for each joint, securely fastened to the rail with channel pins in center of web rail.

**Wiring:**

Hazard Special Railroad insulation or its equivalent shall be used. No. 9 B&S soft drawn copper wire with 5/64" wall rubber insulation, one tape and one braid covering, shall be used for all track connections, track circuits, and for motor circuits. No. 9 B&S flexible soft drawn copper wire with 5/64" wall rubber insulation, one tape and one braid covering, shall be used on battery on elevator in battery chute.

No. 12 B&S soft drawn copper wire with 5/64" wall rubber insulation, one tape and one braid covering, shall be used from line wire to signal and to other local signal or indicator circuits. No. 16 B&S flexible soft drawn copper lamp cord, with 1/16" wall rubber insulation, one tape and one braid covering, shall be used for all local wiring in signal and relay cases.

The ends fastened to the binding post with jamb nuts must be soldered. Nothing smaller than No. 12 B&S hard drawn copper triple braided weather proof shall be used for line wire.

The signal company to furnish all wire, including line wire.

The line wire is to be put up by the signal company on supports, which will be furnished by the Railroad Company. These supports will include glass insulators.

Ariel cable shall be used from pole line into the tower and crossing tracks. Four (4) spare strands must be provided in each cable.

The strand for common wire must be of No. 12 B&S; those for other circuits must be not smaller than No. 16 B&S gauge. All strands must be of copper and have 1/16" wall rubber insulation.

At terminals, suitable cable-box must be provided with a terminal board having slate or porcelain base and brass binding post. All wires leading into this cable box must be connected to the terminal board and protected with lightning arresters.
All aerial wires must be protected by suitable lightning arresters approved by the Signal Engineer. When placed outside, these arresters must be placed in a waterproof iron case.

Suitable ground connections must be made to the lightning arresters, and must be placed at least ten feet in the ground, or more if necessary.

**INSULATING TRACK JOINTS:**

Jebel insulated joints, 2 ft. long, for A.S.C.E. rail of section 3004, shall be furnished by the Signal Company for all insulation in track.

These joints will be applied to the rail by the Railroad Company.

At places where there is not sufficient room to apply the standard Jebel joints, fibre angle plates may be used between the angle bars and rails, and the bolts insulated by means of fibre bushings.

**SWITCH AND LINE INSULATION:**

All switch rod and pipe line insulation required to insulate the track through interlocking plants, shall be furnished by the Signal Company.

**FOULING POINTS ON SWITCHES AND CROSSOVERS:**

Track circuits shall be arranged so that cars inside of tracks must properly clear main tracks before clear signal will be displayed.

On main track crossovers, each switch box shall be arranged to shunt both track circuits.

At Pullman Junction, switches and movable point frogs, as designated on plan, shall shunt track circuits.

**SWITCH BOXES:**

Switch boxes shall be connected with all switches and so arranged that when a switch is in the wrong position or the point is one-eighth of an inch away from main rail, the signal in rear will be thrown to STOP position.

**SWITCH INDICATORS:**

Switch indicators of semaphore pattern shall be located at the stands for all switches not operated by interlocking. Resistance - 10 ohms. The indicators must have separate concrete foundations.

The circuit shall be arranged so that the approach of a train will be
indicated at the switch while the train is at least 2000 feet from the signal, which could be affected by opening switch. Setting point to be second signal in the rear.

TRUNKING:

Substantial wooden trunking must be provided for all runs of wire on the ground and on telegraph poles to the arms supporting the line wire, and must be of sufficient size to leave unused 25% of the inside space provided. Trunking crossing tracks, the top of the casing must be one inch below the base of rail.

Trunking must be painted or dipped in good preservative paint.

Outlets from trunking must be made to arise or bootleg constructed in a substantial manner.

Inside corners of trunking must be rounded.

All trunking, with the exception of that placed on poles, must be run on stakes placed every four feet.

Stakes must be of three inch by four inch rough oak, placed at least three feet in the ground.

CONNECTIONS:

Copper wire must not be fastened to the rail, but the bond wire connections must be run into the bootleg and copper wire spliced to this, and properly soldered and taped.

Two feet slack copper wire must be left at each end of trunking.

JOINTS AND SPLICES:

All joints must be soldered and made by dipping wire into or pouring on the melted solder, wherever practical. Wires at joints must be made in form of regular line wire splice, with turns spaced 1/8" apart. Joints must be thoroughly washed, dried, painted with P&B compound, and must be wrapped with Okonite tape heated and pressed down. Care must be used not to heat taping to injure the quality of material. A coating of P&B compound must be put on over the Okonite tape. It must then be taped with not less than two layers of Grimshaw or some other equally good cloth tape.
TAGGING:

All wires in relay, signal, lightning arrester cases, and on electric locks, must be tagged with sheet fibre discs fastened to the wires with tarred marlin, marked with number and letter to indicate the operating condition, resulting from current being sent through the wires.

LOCKS:

All switch boxes, mechanism cases, etc., will be provided with railroad Company's standard padlocks, furnished by the railroad Company.

PAINTING:

All signal poles, signal pole fittings and ground connections must be painted black.

No paint shall be applied to the outside surface in freezing weather, nor shall any surface be painted unless same is cleaned and dried or until the previous coat has thoroughly dried. Surface covered with rust, grease, dirt or other foreign substance, must be thoroughly cleaned by scraping or other suitable method.

SEMAPHORE BLADES:

Semaphore blades must be 4' 5" in length and painted the Railroad Company standard.

LAMPS:

No. 3 Dressel semaphore lamp must be furnished for all signal arms; back side of lamp must be provided with 1/2" deep hole.

ELECTRIC LOCKS:

At the interlocking plants, electric locks, resistance 100 ohms, must be applied to the levers operating the semi-automatic home signals, and the circuits so arranged that the signal lever shall be locked latch up, with lever normal. Then home signal lever is reversed and an approaching train enters track section 1000 feet in rear of the distant signal.
The signal lever shall remain locked, latch up, until the train has passed the home signal, provided the distant signal has resumed caution and the home signal the normal position.

Electric locks to be of type shown in Union Switch & Signal Company's catalogue, Section II, Plate 1116-A.

The Signal Company shall provide the locking shafts in machine necessary for the attachments to operate the electric lock.

HAID RELEASE:

In connection with each electric lock, an electric hand release shall be furnished and so arranged that the electric lock can be released in one minute, provided the distant signal has resumed caution and the home signal the normal position.

Hand release to be of type as shown in Union Switch & Signal Company's Electro-Pneumatic catalogue, Plate 3915, Fig. A.

TOUR INDICATORS:

In connection with the semi-automatic home signals at State Line - Burnham; Calumet Drawbridge; 112th Street; Burnside and State Street interlocking plants; indicators of the semi-home type with three points, 1000 ohms resistance, enclosed in iron case, shall be provided and located in the tower to be used as stick relay control for the semi-automatic home signals, and to indicate that the track section in advance of home signal is occupied by train.

TOUR WIRING:

All wiring inside the tower must be run on porcelain cleats or knobs.

DETAIL CIRCUITS:

In connection with the circuits on home signals at interlocking plants, with the exception of Fullman Junction and on the mechanical home signal at Raymond Junction and State Line, the relays controlling the slot and motor circuits shall be controlled by an independent circuit and battery.

The circuit shall be opened and closed through a switch box connected with the facing point derail.

TROLLEY CROSSINGS:

At trolley crossings, the track circuits shall be arranged so that the batteries feed from the crossings in all cases.
At Hammond Junction, on lever operating the top arm on mechanical home signal, electric lock and slow hand release shall be provided.

At State line, on lever operating the top arm on mechanical home signal (marked B on Plan) electric lock and slow hand release shall be provided.

At Calumet Ironbridge, suitable electric bridge couplers shall be provided to control the circuit passing through the rails over the bridge.

Plans of the electric bridge couplers and of the circuits proposed to be used in connection with the block system shall be submitted with the proposal, for the Engineer's approval.

Signal circuits to be same as Pennsylvania Lines West, in all respects not noted in above specifications.

Plans on catalogue, illustrating the type of signal, indicators, switch boxes, battery wells, battery chutes, relays, boxes, lightning arresters, and storage batteries, shall be submitted with the proposal.

All work must be done under the supervision and to the satisfaction of the Signal Engineer of the Railroad Company. The foreman to install the plant must be satisfactory to the Railroad Company.

In order that these specifications may be clearly understood, each clause will be taken up and explained and supplemented by a description of the material or mechanism directly connected with it.

A copy of the Plan dated March 2nd, 1907, referred to in the first paragraph of the specifications, is herein inserted as Fig. 1. This plant shows the complete layout of tracks and the location of the signals to scale. Each track is represented by a single line, and the arrows added show the direction of traffic. The signal system
starts at signal 211, on the southbound passenger track and at signal 245 on the northbound track. The point, as a whole, is self-explanatory, with the exception of a few points which will be taken up.

At Pullman Junction, the freight tracks and passenger tracks join, there being but two tracks south of this point. These two tracks cross the tracks of the Baltimore & Ohio, and also those of the Nickel Plate Railroad. These two crossings are not interlocked but the movement of trains is controlled by gates. The switches and movable joint frogs of the junction, however, are in a sense interlocked. The signals alone are controlled by levers in the tower, but all switches and movable joint frogs are thrown by hand; and, on account of locks introduced into the lines governing the signals, insure that they are correctly set before a signal can be cleared. All trains are required to stop on account of uninterlocked crossings, and, since these crossings are in the block governed by signal 21 southbound and signal 214 northbound, the indications of these two signals are restricted to the 45 degree or caution position.

It will be noted that signals 215 and 214, signals 215 and 216, and signals 217 and 213, are placed on a single pole on the same side of the track. These poles are known as bracket poles and the reason for their use at these points is that the Nickel Plate road, after crossing the C. & O. R. R. at Pullman Junction, runs
Parallel to it as far as signal 319 shown. The tracks are so close together that sufficient clearance for the ordinary straight pole is not given, and the three signals affected were necessarily placed on the wrong side of the track. Signals 215, 315 and 317 govern the south-bound track while signals 216, 216 and 218 govern the northbound track. The construction of the different types of poles will be shown later.

It will also be noted that the semi-automatic signal, 319, at the interlocker at 112th Street, is placed on an offset pole. This pole is of the same construction as those above and is used at this point so as to place the signal out over the track, as the view from the north is obstructed by a high board fence running close to the track.

The purpose of the switch boxes designated on the plan is to insure that switches are set in the correct position for the main track. If a switch be set in the open position, its switch box interferes with the circuits of the signal governing this switch in such a manner that it is thrown to the stop or danger position, in which it remains until the switch is properly set.

The purpose of the switch indicator designated is to indicate to a person at the switch whether he may safely open it without interfering with an approaching train. The manner in which this is done will be explained when the signal circuits are taken up.
Fig. 2, Fig. 19, shows a side and front elevation of a completely assembled block signal on its foundation. Referring to letters, a is the concrete foundation 21' square at the top, 22' square at the bottom and 5' deep. Embedded in the concrete, are the four foundation bolts, bb, of 1' round iron, 30' long, with a hook of 4' length on the end.

The mechanism case, c, is held to the foundation by the four hook bolts. This case contains the operating mechanism. The doors, d, allow access on two sides. The latches, e, are arranged with eccentric lugs which press the doors tightly against the case. Rubber tube gaskets are used, which make the case water tight. For ventilating purposes, a small opening, with overhanging covers, is provided at f.

The pole proper sets u on the mechanism case and is held by the four bolts, g. The base, h, is cast iron. The pole, i, is placed in it and lead filled in to make it secure and water tight.

The bearing casting, j, sets down over the top of the pole and is held in place by set screws. This bearing contains the connections with the mechanism in the case at the base. The shaft, l, turns in phosphor bronze bearings and is driven by connections within (this will be explained later in detail). The protruding end is squared to receive the casting, i, commonly known as the 'spectacle casting.' It is held u on the squared portion by a nut and cotter on the outside. This spectacle c. s.
ing carries the blade, \( m \), which is on rod. The spectacle casting, with the blade, is free to move with the shaft, \( k \). Their movement is limited by stops to 90 degrees. As shown in the figure, the blade is horizontal. It can not move any higher but can be pulled downward through 90 degrees, or vertical when it becomes parallel to the pole. The bracket, \( n \), is used to support a lamp, which is located behind the openings, \( o \), \( p \) and \( q \), in the spectacle casting. That is, in the horizontal or position shown, the light would be seen through the opening, \( o \); the lamp being stationary, if the blade is moved downward 45 degrees, the light shows through opening, \( p \), while with the blade in the vertical position, the light shows through opening, \( q \). The indications specified are given by the blade by day and the light by night. The top of the pole is closed by the casting, \( r \), called the pinnacle casting. This makes a watertight pole and gives it a finished appearance. Access to the top of the pole is obtained by the ladder, \( s \), held in place by the braces, \( t \), and the cast iron foundation, \( u \). Referring again to the indications, opening \( o \) in spectacle casting \( l \), will carry a red glass; opening \( p \) will carry a green glass, and opening \( q \) is left entirely open. Thus, with blade in horizontal position, the light behind the red glass in \( o \) would show red, indicating block ahead occupied; with blade in 45 degree position, the light would show green, indicating block ahead unoccupied but second block ahead occupied; and with blade in vertical
position, the light would show white, indicating first and second blocks unoccupied or clear. A block may be defined as that section of track between two consecutive signals.

Blade, m, with spectacle casting, l, is rotated about shaft, k, by supplying current to the motor driving the mechanism at the bottom of the pole. They may be stopped either at 45 degrees or 90 degrees, by cutting off the current from the motor. The blade, however, is held after the motor is cut out by the current either in the 45 degree or 90 degree position. If this current be cut off in any way, the weight of casting, l, is sufficient to return it with blade to the horizontal position. This position is also known as the stop or danger indication, so that failure of any part will cause gravity to place the spectacle casting and blade in the danger position, which means safety for the train whose engineer heads it.

The semi-automatic signals at interlocking plants are the same as the automatic signals, in the exception that they are under the combined control of the train and the lever-man in the interlocking tower. That is, as far as the train on the track is concerned, they operate like the other signals, but it is necessary for the lever-man in the tower to close the circuit, which will cause the motor to pull the blade down from the horiztonal position.

In order to show to the engineer the difference between an automatic signal and a semi-automatic signal,
a second is placed on the same pole as the signal
the semi-automatic are. The semi-automatic are, therefore, is the top arm on the pole, and governs movements on the main track through the interlocking plant. If there are switches in the interlocking plant over which movements may be made from the main track, then the lower arm governs such movements, and is controlled by a mechanical connection to the lever in tower. If no such movements are possible, then the lower arm is fixed in the horizontal position, and merely shows the function of the semi-automatic arm.

The normal position of a signal may be defined as that position in which a signal should stand if no train be considered. Thus the automatic signals stand at 9° degrees, indicating clear, while the semi-automatic signals stand at horizontal or stop position.

The top bearing casting, referred to in the general description of the signal pole, is shown in the figures Nos. 6 and 7. Fig. 6 shows a side elevation partially broken away, disclosing the working parts within. Fig. 7 shows a front elevation with a half section through the center of the semaphore shaft. Referring to both figures, pages 24 and 25, the segmental sheave, c, has a square hub, b, which works freely between the bearing bosses, c, and d, with no unnecessary end play. The shaft of the shaft, e, passing through the hub, b, is square so that the shaft and sheave must turn as one. A short length of bicycle chain, f, is secured to the upper end of the
sheave groove by the lugs, g, on either side. To this chain at either end is fastened the wire which connects with a similar chain on the driving drum of the mechanism. Upon the square hub of sheave, c, is fitted the buffer arm, h, which also must move with the sheave and shaft. The bearing bosses are bushed with the phosphor-bronze bushings, i, and j, held in place by the cap screws, k. The part of the shaft projecting is squared for a short length, l, this squared portion being tapered from 3/4" at the small end to 7/8" at the large end. The part, m, is threaded for a standard 3/4" nut. As stated above, the spectacle casting is fitted to the square shaft, l, and held in place by a nut on the end, n. Referring especially to Fig. 6, page 24, the buffer crank, h, acts against the piston, n, of the dashpot, o. The dashpot is open only at the top and covered by the cap, p, which is pulled down on a gasket by three cap screws, making an airtight joint. Into the top of the cap is screwed the check valve, q, which is adjustable and acts in such a manner that when piston, n, drops, air will be freely admitted into the cylinder; but, when the force of the arm, h, is thrown upward against the piston, air is allowed to escape very slowly, thus checking the movement of the arm, h. The upward movement of the arm and segment is adjusted by the screw, r, which is screwed into the body of the casting and strikes against the segment, a. The downward movement is adjusted by the screw, s, which strikes
against the lower side of the sheave. These screws are adjusted when the spectacle casting is in place. Screw, r, permits blade to rise until it is horizontal, while screw, s, allows blade to be pulled down if it is vertical.

Considering the blade and spectacle casting in place, the parts of the top casting operate as follows: On account of the weight of the spectacle casting, the parts will take the _position as shown in Fig. 6, i.e., the blade horizontal, the sheave resting against the stop screw, r, and the buffer arm, h, holding _iston, n, at the top of the cylinder. Now, if a downward force is applied to the lower end of the chain, f, the sheave, e, rotates, driving the shaft, e, with spectacle casting and blade, and the buffer arm, h. The _iston, n, of its own weight follows the arm, h, to the lower end of the cylinder, air being freely admitted to the top by the valve, q. If the force be released at any point of the stroke, the weight of the spectacle casting returns the parts quickly to the position shown until the buffer arm again strikes the _iston, n, compressing the air in the top of the cylinder, which checks the heavy weight and allows it to sink easily into its _osition against stop screw, r, as the valve, q, allows the air to escape slowly from the cylinder. This is the operation for any position between the limits of the stop screws, r and s. Access for oil and repairs is made through the door, t, which is held firmly against a rubber gasket by a screw at its bottom.
The operating mechanism of both automatic and semi-automatic signals is shown in Fig. 3, page 23.

Three views of the mechanism are shown, i.e., both ends and one side elevation. It consists of a motor; a train of gears; a magnetic clutch; a magnetic brake; and a circuit controller. The motor is shown at a. It is series wound 1/20 h. p. at 11 volts and 13. 1. I. It is entirely enclosed and is practically watertight. The commutator is covered with a glass cover so that it can be inspected without opening. The brushes are radial and made of rolled copper gauze. The train of gears consists of the motor pinion, b, of 1" pitch diameter, and 3. diametral pitch. This pinion meshes with a 3" phosphor-bronze gear, c, of 1/3" face. This 3" gear drives shaft, d, which is 2/3" in diameter and has a 1" pinion, e, of 1/2" face and 1" diametral pitch cut from one piece. This shaft runs in a single phosphor-bronze bearing pressed into the frame.

Meshing with the intermediate pinion is the 2" phosphor-bronze gear, f, which in turn drives a 3/4" shaft in a phosphor-bronze bearing, having the main driving pinion, g, of 1" pitch diameter and 16 diametral pitch cut on it. This main driving pinion drives the 3" gear, h, which runs on a projection of the phosphor-bronze bearing pressed into the frame as a bearing for the main shaft shown at i. The 3" gear, h, drives the armature of the magnetic clutch, j, by projections on its hub. This affords a positive drive, but without rigid connection, leaving the armature free to adjust itself horizontally against
the face of the clutch. This armature is hidden by the brass shield, k, which is attached to clutch, j, and projects out over the armature so as to protect it from dirt. The shield, however, does not touch the armature at any point. The armature and clutch present perfectly flat services to each other.

The clutch, j, is simply an ironclad magnet. It is made of borax iron. It is 6 1/2" outside diameter and bored to fit the 1-1/8" shaft, i, to which it is rigidly connected by the taper in, l. The diameter of the inner pole is 2-7/8", while the inside diameter of the outer pole is 5-5/8". The winding space is bored to a depth of 2-1/8", leaving a back on pole 1/8" thick connecting the inner and outer poles. This clutch contains a double winding; one consisting of a coil of 83 turns of 13 M&H gauge double cotton covered wire; the other, 875 turns of 27 M&H single silk covered copper wire. Connections to these coils are made through the slip rings shown at m. There are three of these; one, making connection to one terminal of the 37 coil; one, connecting with one terminal of the 13 coil; and the third affording a common connection for the remaining terminal of both coils. These are respectively reached through the brushes, n, o and p. The coils are so arranged as to produce the same magnetic polarity when current is passed through them, so that when energized at the same time their magnetic effects are combined.
The shaft, i, extends through the magnetic brake shaft, j, which is fixed to the frame by the cap screws d, r, and carries the movable disks, s, t, u, v and w, which make u a part of the circuit controller. The stationary brushes are arranged in three rows 45 degrees apart, shown at x, y and z. The disks of the circuit controller consist of a cast iron hub, ss, keyed to shaft, i; the fibre disc, bb, fixed to hub, ss, carrying on each side an 180° phosphor-bronze segment, cc, riveted together through the fibre. Each of the contact brushes at a, x, y and z, is constructed in a horseshoe shape so that it springs down over the phosphor-bronze segments and fibre disks, making contact when on the phosphor-bronze segments, and breaking contact when segments pass from it. Wire connections are made to these brushes by means of the binding posts which hold the brushes in place. Circuits are made between brushes in one row and brushes in another, which make contact on the same disk as the shaft, i, turns. These brushes are units and may be arranged in any manner desired. They are held in place by the long cap screws, dd, which pass through the fibre insulators and screw into the brass bracket, ee, fixed to the bracket, i. A row of brushes may be removed by unscrewing two of these cap screws and lifting them out.

The magnetic brake is shown at the back of the motor. The two brass standards, ff, are fitted over the ends of the magnet and carry the arms, hh, to which are attached the adjustable swiveled brake shoes, ii. To the lower
end of each of the brake arms is attached circular structure, jj, while the upper ends are connected by the tension spring, kk. The magnet, gg, is also of the ironclad type, made by winding 51 turns of 11/32 covered wire on a 5/8 iron core, and placing inside of it iron core. The core and wire project slightly beyond the brass supports at each end. This brake is operated in series with the motor so that when the current is supplied to the motor, the armatures on the brake arms are attracted to the core and the brake shoes, ii, are pulled away from the brake wheel, ll, on motor shaft against the force of the spring, kk, and motor armature is released. When the current is again cut off, the brake armatures are released and the spring, kk, causes the brake shoes to again clamp the brake wheel, holding the motor armature stationary.

To suit the operation of this mechanism, the brake coil and 11/32 wire coil of the clutch are connected in series with the motor, while the 1/37 wire coil of the clutch is connected in parallel with the motor circuit. Both circuits may be cut off and on as desired, by adjusting the circuit controller. The motor drives the armature of the clutch through the train of gears. Unless the clutch coils are energized, the clutch and shaft will remain stationary, if current is supplied to the motor alone. But, if the motor current is taken through the clutch coil and brake coil at the same time, the shunt coil is also connected across the line and the clutch is energized, attracting the armature to it. The friction
between the faces in contact then causes the clutch to move, driving the shaft. The clutch is then used as a drum about which a chain is wrapped, giving the pulling power which operates the signal arm described above, through a wire connection. Then the arm is in the position desired, the motor circuit is broken, while the shunt coil remains energized, holding the arm in that position. If the current be cut off from the shunt coil, the clutch releases the armature and the blade returns to the horizontal position as described above. The part which the magnetic brake plays is to prevent the gears from drifting backwards, on account of the weight of the spectacle casting, when the blade is held in the 45 degree or 90 degree position.

It will no doubt surprise the readers when they know that the tension on the connecting wire in actual operation is about 150 pounds, and that when clutch is energized, under operating conditions, it would take a weight of about 20.3 pounds to separate the clutch and armature faces. It should be born in mind that the only force acting to drive the clutch and shaft is the friction between the armature and clutch faces, when the clutch coils are energized. This is the foremost feature of the entire mechanism. The following diagrams of circuits will make clear the exact wiring used in this installation as a three position mechanism.
Fig. 4. page 56, shows in diagramatic form the internal circuit for the three position scheme.

The battery, o, supplies the current at a pressure of 10 or 12 volts; the disk, f, carried on the clutch shaft, controls the current through the shunt coils of the clutch; while the disk, g, controls the motor circuit. The switches, f and g, show the manner in which the current must be delivered to the circuit controller. If switch, f, be closed, but g left open, the motor circuit is closed through contact brush, l; phosphor-bronze segment, i, of disk, g; contact brush, j; through brake coil, m; over, n; contact brush, t; phosphor-bronze segment, c, of clutch; series coil, e, of clutch; phosphor-bronze common segment, c; to negative battery. At the same time, a parallel circuit is closed through contact brush, i; phosphor-bronze segment, s, of disk, f; contact brush, h; contact brush, v; segment, a; shunt coil of clutch, d; common segment, b; contact brush, u; to negative battery. The motor runs, driving the train of gears as explained above, and, as both clutch coils are excited, the clutch attracts the armature and is driven by it, moving the shaft, and consequently the circuit controller disks, f and g. The chain connection winds about the clutch, causing the drum, of same diameter, in the top bearing on the semaphore shaft, to rotate with it, thus driving the spectacle arm and blade through the same angle that the clutch moves. This motion continues until shaft turns through 45 degrees,
Then contact is broken between brush, i, and segment, r, of disk, g. This cuts off the motor and the mechanism stops. Disk, f, is adjusted so that brush, i, and segment, s, contact when shaft has moved 30 degrees, or 2 degrees behind the breaking point of brush, i, and segment, r, of disk, g. Thus the shunt coil remains energized and the clutch still holds to the armature until the blade is at an angle of 45 degrees. Now, if switch, k, be closed, the motor circuit is again closed through brush, k, and segment, r, on disk, g, and the motor again starts. The armature turns through one half arc and carries the blade 45 degrees. The contact is again broken at k. Since brushes, h and l, are just 45 degrees apart, the clutch moves through 45 degrees and the blade is turned through a 45 degree angle. Lacing it in the vertical or 90 degree position when contact is broken at k. The shunt coil is energized at all times direct from the switch, k, thus holding the blade in the 90 degree position after the motor is cut out, as long as k and _ remain closed. If k is closed, the shunt coil circuit will be broken, the clutch released, and the blade will return toward the horizontal position until it comes to the 45 degree position, then contact is again made at brush, h, on disk, g, and contact, i, on disk, f. The motor is at once cut in and operates until the blade is returned to the 45 degree position, the sight of the spectacle casting having caused the clutch to slip slightly at the 45 degree posi-
tion toward the horizontal. If so, the clutch acts as a cushion and there is no noticeable jar on the mechanism. If switch, \( L \), is closed, \( L \) is evident that all current is cut off from the mechanism, and the blade and spectacle costing return to the horizontal position as described above. If switches, \( L \) and \( L \), are both closed at once, the mechanism completes the entire 90 degree stroke without stop. It is seen that all current for the 90 degree position must pass through the 45 degree position switch, i.e., switch, \( L \), must be closed before the closing of switch, \( L \), will have an effect on the mechanism. The reason for this will be seen when the circuit is laid to the track control.

The direct application to the track is shown in diagramatic form in Fig. 5, page 39. This will show the first step in the working out of the entire circuit plan of this installation.

Three signals have been represented in Fig. 5; i.e., one in each of the three positions. Signal on \( L \) is at "stop" or "danger"; signal \( L \) is at 45 degrees or "caution"; and signal \( L \) is at 30 degrees or "clear". The sections of track, \( L \), \( L \), and \( L \), between signals, are "blocks". The condition represented by the three signals is that of a train in block \( L \), pointed out in the specifications. The diagram has been lettered for clearness the same as the diagram of Fig. 4. It will be readily seen that the only change is that the hand throw switches, \( L \), and \( L \), of Fig. 4,
have been replaced by the magnetic switches, D and E. In the signal world are known as "relays". It is thought best that these relays be described at this time so that the circuits of Fig. 5 may be more easily understood.

The relay used is of the enclosed type and is shown assembled in Fig. 9, page 31, and Fig. 9, page 45. The base, a; the top, b; and the coil to c, are moulded into shape from a special insulating compound. The glass cylinder, d, is clamped between a and b by two bolts which are sealed in place, taking all joints watertight. The magnet cores, e, are of round Norway iron, 5/8" in diameter, turned from 1" square iron, so that the pole faces are 1" square. They are fixed to the moulded top by countersunk head screws put through from the top, and screwed into the core on the under side of the pole face. The coils, f, are wound on brass spools with enameled wire, and are enclosed in a hard rubber casing. They are placed down over the cores, and are held in place by the iron yoke, g, which is clamped against the shoulders of the cores by the nuts, h. The moulded coil to c, supports the binding posts, i, which are the terminals of the coils in series. The coils are connected together at the binding post, j, shown in Fig. 9. This same post, j, serves to bolt the two coils together so that they may be handled as one piece without breaking any connections.
To the pole cores is fastened the armature \( \text{c} \), \( \text{d} \). This is of brass and extends from one core to the other, having a single screw into both. The armature, \( \text{e} \), is pivoted on the beryllium silver screws, \( \text{f} \), \( \text{g} \), (one on each side). Projecting from its under side are the beryllium silver studs, \( \text{h} \), supporting the copper connecting strips, \( \text{i} \), the back ends of which are connected by flexible copper connections, \( \text{j} \), commonly called 'spider wires', to the binding posts, \( \text{k} \), clamped into the moulded top. The front ends of the connecting strips, \( \text{i} \), carry the front spring contact points, \( \text{l} \), which are tipped with tin, also the back spring contacts, \( \text{m} \). As the armature is down, the back spring contacts rest on the copper bars, \( \text{n} \), which are held by the binding posts, \( \text{o} \), which are also clamped to the moulded top. The front spring contacts are lifted against carbon cylinders, \( \text{p} \), held in place by the binding posts, \( \text{q} \). Thus, with the armature down, a circuit is closed through binding post, \( \text{q} \); spider wire, \( \text{r} \); connecting strip, \( \text{s} \); back spring, \( \text{t} \); bar, \( \text{u} \); and binding post, \( \text{v} \). If the armature is attracted by the cores, the contact strips are lifted and the circuit is transferred from binding post, \( \text{u} \), to binding post, \( \text{w} \). The first is known as a 'back point' contact; the latter, a 'front point' contact. Thus, all relays used in this installation have three front points and two back points.

The features of this relay are its compactness and the ease with which the coils may be changed. Fig. 10,
Page 46, shows the top with yoke and coils removed. It is to be noted that this constitutes what might be considered all working parts, and they are all fastened to one and the same top. There is no chance for any part to change its position and thus destroy adjustments. Fig. 11, page 46, shows the form, round coils removed. The resistance of these coils varies as desired and it is evident how easily one may be replaced by another without disturbing any part or adjustment. The line relays used are of 1000 ohms resistance, while the track relays are of 4 ohms resistance. Each relay requires about 70 mil-amperes to pick up its armature with the weight of the joints.

Returning again to the circuit diagram, Fig. 6, page 39, the relay, D, which replaces switch, p, of Fig. 4, is a 4 ohm track relay. The relay, E, which replaces switch, q, of Fig. 4, is a 1000 ohm line relay. As pointed out above, these relays are identical with the exception of the coil resistance. Relay, D, at signal 3, is operated by the battery, F, at signal 2, the circuit being made through the rails of section A. Sections A, B and C, are separated from each other by the insulating joints, H. Relay, E, at signal 5, is operated on the following circuit: starting at signal 3, positive side of battery C; front joint, k, of relay, D; contact brush, w; phosphor-bronze segment, y; contact brush 2 of added disk, x, (disks, x, and brushes, w and z, are the same as disks, f and g, described above); by the line wire, k, to signal 3 through coil of relay, F, to line wire, I, and back to negative side of battery.

INSTITUTE OF TECHNOLOGY
LHASA,
at signal 3. Disk, $x$, of signal 1, 2, and 3, is arranged to close the circuit from $w$ to $z$ when the signal blades reach the 45 degree position and it remains closed thereafter. It will be noted that disk, $x$, of signal 1 closes the circuit for relay, $E$, of signal 2 to the battery of signal 1. Thus, the relay, $E$, controlling the battery supply to the signal mechanism, and the 45 degree position is governed entirely by the conditions of the track section to which it is connected. Relay, $D$, controlling the 90 degree position for any signal is governed by the position of the signal directly ahead of it, which must reach at least the 45 degree position before current is admitted to its circuit. Thus, for any signal to display the "caution indication", 45 degree position, the current from track battery, $F$, must energize the coils of relay, $E$, attracting its armature and closing the front contacts as indicated; and further, for this signal to display the clear indication, 90 degree position, current from the next signal ahead must energize the coils of relay, $D$, attracting its armature and closing its front contacts as shown. It has been pointed out that the signal controlling relay, $E$, must be at caution or 45 degrees before current is admitted to it. Now, if a metallic connection of negligible resistance be connected from one rail to the other, of any section, it is evident that the battery, $F$, would be practically short-circuited. As a result, the coils of relay, $E$, would be deenergized and its armature would drop, breaking the front contacts and cutting off
all current controlled by them. In actual operation, the metallic connection from rail to rail is made by the axles of engines and cars; in this manner, they control the action of the signals.

Thus, as long as the track circuit of section, A, is not interrupted, the front points of relay, D, remain closed and signal, S, could be held in the caution or 45 degree position; and, as long as the track circuit of section, B, is not interrupted, the front points of relay, D, signal 1, could remain closed and signal 3 would be held in the 45 degree or caution position; but signal 2 in 90 degree position closes the circuit of relay, D, of signal 1, which is pulled down and held in the 90 degree or clear position. Thus, for signal 3 to indicate caution, section or block A must be unobstructed. Therefore, for signal 3 to indicate clear, sections or blocks A and B must both be unobstructed.

With these conditions, the train in block, C, causes relay, D, signal 1, to open, breaking its front contacts, and signal 1 assumes the stop or danger position. In doing so, it breaks the circuit of relay, D, signal 2, and signal 2 assumes the caution position and signal 3 takes the clear position. In this manner, the indications specified are obtained.

In this installation, the battery, C, in each case, consists of six cells of 5 D storage battery connected in series, made by the Chloride Accumulator Company. These are of 40 ampere-hour capacity, and one set is provided
for two signals when not more than 300 feet apart. Otherwise, one set is provided for one signal. The trial battery, F, consists of three cells of ordinary gravity or blue vitriol battery connected in parallel.

In parallel with each set of storage battery is connected a set of 16 cells of trial battery in series connection; that is, three cells of gravity battery are provided for each cell of storage battery. The gravity battery is used to charge the storage battery. While it does not have the current capacity to operate the signal mechanism, it can replace the energy taken out by the operation of a signal, at a low current rate, for the longer time between signal operations. The gravity battery will deliver a steady current until it is completely exhausted, then it must be renewed.

All storage battery, with its charging set of gravity battery, and all trial battery, wherever possible, are kept in concrete battery cells or vaults, cylindrical in shape, being 5 feet diameter and 7 feet high inside measurements. An opening is provided in the top, about 24 square, which is covered by a galvanized iron cover, arranged to be locked in place. Three shelves are provided, which extend around the whole circumference of the cell. They are cut in segments, which square radial ends, and are only supported on the underside. They are otherwise self-supporting, on account of their arch construction. Thus, the weight of the battery does not come on the nails and screws used.
The battery vaults are sunk in the ground until their tops are level with the top of the track rail. They weigh about 3000 pounds each and are provided with four hooks on an iron band about the bottom, for handling. They were lifted from the car and lowered into the hole prepared for them, by a wrecker crane.

In places where track battery cannot be placed in battery wells, cast iron chutes are provided. These chutes are 7 feet long and about 12 inches in diameter. They are placed 6 feet in the ground, and the battery is raised and lowered by means of an elevator and pole. They are used in this installation at the street car line crossings and at the ends of the line where no battery vault is used. They are also used in connection with the relay boxes at the advance locking sections (these are explained later), where they not only shelter the track battery but also serve as a foundation for the relay box. This combination is shown in Fig. 13 and will serve to explain both chute and relay box.

Fig. 13, page 51, shows a sectional view taken through the center of the relay box, battery chute and elevator. The chute, a, is placed in the ground to the shoulder, b. It is covered by the cast iron cover, c, a plan view of which is shown in Fig. 14. Within the chute at the shoulder, b, is placed the circular board, d, which makes a comparatively tight joint with the shoulder of the chute, and is called the frost board. Its purpose is to make that portion of the chute below the ground line
as tight as possible so as to lessen the amount of the battery below freezing. The rope, e, is suspended from the frost board and attached to the top of the elevator, f. The elevator has three shelves, g, h and i, each of which supports one cell of the track battery. The shelves are held together by the three slats, j. The elevator, i.e., its battery, may be drawn out of the chute or be kept in. In the back of the top of the chute, an opening, k, is made, so that the wire to be run to the battery. When the chute is used alone, these wires are led directly through the trunking, l, and outside, m, to e, that is, in closed casing. Otherwise, casting supports the cast, a, or 2 wrought iron (e.g., which supports the relay box, o, at its top.

The relay box, o, is made in sections. It consists of the base, h; middle section, f; top section, i; back section, s; and door, t. A wooden box, u, is fixed inside of the cast iron box, and the door, t, is also provided with a wood lining on springs, which, when the door is closed, depressed lightly by just the wooden box, i.e., makes a dust-proof casing. The back section, s, is 1 1/2" thick, lining 2" inside diameter, and bolts directly to the back of the middle section, u. The reason for making each section removable is to facilitate running the wires into the box. These wires must pass up through the top and run through small openings in the box at the middle section, through the wood lining, and to the relay.
The object in using the box, t., is to facilitate the removal of the sections, i., e., that, due to any number of the sections, i., e., wires, with due care, t., may be placed upon each other, of the top, t., placed on the hole, thus giving but one place of holding any number of relays desired. A front view of the relay box and the top of the battery chute is shown in Fig. 15.

Since the track circuit maintained for each block or section is the most important part of the installation, as it is through this that the control of the signal is with the train, great care must be taken to give the current its best path through the rails and relay coils. At each joint, the rails are connected or bonded together by two 
\(\frac{1}{2}\) Eel Galvanized iron wires, 32' long, that are connected to the rails by drilling holes through the rail at each as close to the end of the fish plates as possible, putting the end of a wire through each and plugging them with channel nuts. The channel in is of stock \(\frac{1}{4}\) in. in diameter at one end, \(\frac{3}{16}\) at the other, and 1 long. On one side a groove is cut, called the fuse slot, just large enough for the \(\frac{1}{32}\) wire to curl itself until it is within the circle of the \(\frac{1}{4}\) and \(\frac{3}{16}\) ends. The \(\frac{1}{2}\) in is inserted into the hole in the rail from the opposite side of that from which the wire is inserted. The \(\frac{1}{2}\) in is forced tightly into the rail. In account of its taper, it is pressed hard against the wire and the rail, thus giving a good contact. Two wires are used at each joint to make the connection doubly sure, as
They are exposed and subject to rough use by the hands of track workers and section men, in tightening and tapping joints.

The insulating joints used to separate one section from another are known as the "flex" joints. Fig. 10, on the following page, shows an assembled joint, while Fig. 11 shows a sectional view. The track rails are shown as a and b. The ordinary fish plates and bolts are removed, and the plate, c, in the section of rail, d, riveted so it is placed under the rails, a and b. The out lying, e, and the fibre strip, f, are inserted between the rail, d, and the rails, a and b; while the fibre plates, g, is placed between the bottom of the rails, a and b, and the sole plate, c. Bolts, h, extend through rails, a and b, and rail, d, with filler block, i, and the fibre strip, j. These bolts are insulated from the rail, d, and strip, j, by the fibre bushings, k. Between the ends of rails, a and b, a fibre plate 1/4" thick, and cut in the shape of a section, 1 and 2, is inserted a short way into the rails. These are known as end joints. Thus, rail, c, is insulated from rail, d. The object of the reinforcing rail, 3, is to carry the car wheels over the joint, thus leveling rail ends, and will prevent wheels from the wheels, g, from one to the other, preventing the fibre plates, 3 and 4.

The switches in the track sections are insulated by cutting the rods which tie one side to the other. The ends are separated 1/2" from each other and two wrought iron
straps, one on each side. A ribbed plate separates these from the switch rod. Holes are drilled through the straps, fibres and switch rods, and fibre bushings inserted in the holes through them. They are then tinned together and the insulation is complete. A length of the insulating is cut out of the middle of the tie plates, on which the joints lie. These ends are drilled, and each fastened to the tie with the rail clips.

In any places in this installation, switches and derails, which are located on curves or in interlocking plants in charge of other roads, are not insulated as described above, but are simply cut out of the track section by insulated joints. This latter is done in order to preserve the solid tie plates from one rail to the other, on account of the roof tendency for the rails to spread on curves. In the latter case, it is merely a question of maintenance. If the road controlling the interlocking plant has charge of the maintenance, their representatives will not give the attention to the insulation of the switches and derails that they should have; while, if insulated joints are used, the track department must keep these joints in good condition, and no trouble is experienced with the signals operating through such blocks.

All pipe lines controlling switches and derails on the tracks which affect the signals are insulated just as they leave the track, so that no track current may get into the pipe lines and find its way back to the opposite rail.
In the wiring, the specifications were, by permission of the railroa company, departed from to some extent.

7/6 B&S soft drawn copper wire with 3/64 wall of rubber insulation, one tape and one braid covering, was used for all track connections; 7/6 B&S soft drawn copper wire with same insulation was used for the main battery leads from battery well to mechanism; 7/6 B&S soft drawn copper wire, with same insulation, was used for connections to line wire; and 7/6 B&S flexible wire, with same insulation, was used for connections in signal cases and relay boxes, i.e., such connections as are subject to frequent handling. The line wire is all 7/6 B&S hard drawn weatherproof insulated copper wire, with the exception of the common wire, which is a 5/2 B&S hard drawn weatherproof insulated copper wire.

Ariel cable was used for crossing the street car tracks and Illinois Central Railroad at Burnside; crossing Rock Island; Nickel Plate and street railway at Pullman Junction; and from pole line to tower at 112th Street Calumet Bridge; East Side and State line, at all other railroad crossings and interlocking towers, wires were run.

The Ariel cable used was of four different sizes, in order to fulfill specifications calling for four extra conductors: one size, consisting of six 7/16 B&S and one 7/6 B&S copper wire; one consisting of nine 7/16 B&S and one 7/6 B&S copper wire; one consisting of eleven 7/16 B&S and one 7/6 B&S copper wire; and the fourth consisting of fourteen 7/16 B&S and one 7/6 B&S copper wire. At the
terminals of the cable, standard copper wire cable ends were used, and the lightning arresters for protecting the cable placed in them.

The lightning arresters used are of the choke coil type. The coil is wound around glass tubing which is filled with iron wire and is supported at each end by a small brass casting, both of which are fastened to a slate base 1 inch wide and 5 inches long. The ground plate runs under the coil and is separated from it by a thin piece of perforated wire. At the ends the ground plate is notched and points placed close to the brass terminals. These brass terminals also serve as binding posts. They also support an insulating strip carrying a third binding post. A fuse of the same capacity is connected from the middle post to either end. The line wire is connected to the binding post, and the circuit goes from the line through the choke coil, then the fuse, and to whatever connection desired.

A 7/8-in. insulated wire is used for a ground wire. It is connected to all the ground plates of the arresters, led out and plugged and soldered to the top of a one-inch galvanized iron pipe which is driven into the ground to the depth of ten feet. This is a sufficient depth for all places, as the ground is very low, and wet quicksand may be reached at from 2 to 4 feet under the surface.

In order to protect the main tracks from cars on the side tracks, the rails of all switches are connected in parallel with the rails of the main track, as necessary.
the clearance of main joint. Insulated joints are inserted at that joint, and it is necessary that cars be placed behind these joints in order that the signal overlying the immediate block may not be interfered with. At the point of the switch, which is closed when the switch is set for the main track, a switched circuit controller commonly known as a "switch box." This is so arranged that when the switch point moves a distance of 1/2", it breaks the track circuit, and at the same time connects the rail with the other, thus shorting the coils of the relay as well as cutting the battery circuit. A diagramatic sketch of this arrangement is shown in Fig. 17, page 11.

The track section, A, is limited by the insulated joints, c, at one end and the insulated joints, d, at the other end. The battery, h, supplies the four coils of track relay, e. At the switch, c, the insulated joint, e, is installed in the main track rail, l, and the joint, f, in the side track rail, h, as close to the switch point as clearance will permit. Just back of the joint where the sidetrack becomes parallel with the main track, the insulated joints, g, are placed. These joints mark the fouling point of the switch. The wire, j, connects rail, h, with rail, l. The rods of this switch are not insulated as pointed out above in discussing interlocking switches; but the insulation is accomplished by the use of a wedge, m, which is so placed on the tie that when the switch is set in the normal position, the open joint, q, is lifted.
so that it does not touch the rail, I, at any point. The tie plate is cut in the same manner as in interlocking switches.

The contact points of the switch box, B, are shown at o and P. It is noted that the contact bar, r, makes a circuit around the insulated joint, e, in rail, I; while the open contact, P, has one side connected to each rail. If r be moved from o, it breaks the track circuit which would cut all current from the coils of relay, a. At the same time, if r is moved so as to close the contact, P, it is evident that this would shunt the coils of relay, a. This gives double protection, as either would accomplish the result desired and both could have to be out of order to fail completely. The movement of r is controlled directly by the closed joint, n, and it is only necessary that n be moved 1/8" to accomplish the full movement of r, with the above result.

The switch box, B, is shown in Fig. 13. The plan view shows a row of four controlling disks, the maximum number for which it is designed. These disks, a, and contact brushes, b, are the same as used on the circuit controller of the signal mechanism, and, therefore, these parts are interchangeable. The disks, a, are fixed to the shaft, c, which operates in babbitted bearings, d, and e. The contact brushes, b, are supported by the cap screws, f, which are threaded into the side of the case. Wires are brought into the box through the openings, g, under the binding posts of the contact brushes.
The outer end of the shaft, c, is slotted out to make room for the steel rollers, k, and i, which turn on screws fixed into the shaft. The crank shaft, j, carries the cams, k and l. These are two castings from the same pattern, turned back to back, so that their plain sides are together. Their hubs are split, so they are clamped to the shaft by bolts, m. They may be adjusted, therefore, to any position desired, to the limit at which lines, k and l, coincide, which is the Limits. Throw entered.

Crank, j, fits a, on a taper squared portion of shaft, c, and is held in place by a nut and cotter pin. To operate the controller, consider crank, j, moved to the right. The shoulder of cam, k, engages the roller, i, and moves it downward, causing shaft, c, to rotate, carrying the disks with it. This rotation continues only until roller, i, allows cam, k, to pass it. In this position, both sides, h and k, bear on the circular surface of cams, k and l, thus locking shaft, c, in this position. As crank, j, moves, at the end of the stroke, the projecting portion of cam, k, strikes roller, h, driving it downward and rotating shaft, c, in the same direction. The action is the same on the reverse move.

As pointed out in the circuit diagram of Fig. 17, all the contacts are moved by the first motion of the switch, so that it is only necessary to adjust cam, k, as shown, and place cam, h, at its extreme position so that it will not engage roller, h, at the end of the stroke, but will leave both rollers locking the position of the shaft, c.
Contacts are made in the signal box by a brush on one side through the disk set and to a brush on the other side. The disks may be adjusted as desired, to get the requirements pointed out in Fig. 17. The connection to the switch point is made by a rod from the lower end of the crane, y, directly to a lug on the switch point. The box is provided with the lid, w, which when closed makes a watertight joint on a felt gasket. It is locked by means of the hasp, r. The box is bolted to the switch tie, about three feet from the rail.

At each of the outlying switches, five in number, is located a switch indicator. This indicator is of the semaphore type and is a miniature signal enclosed in an iron case and operated electrically. They are placed on an iron pipe held by a cast iron base bolted to a concrete foundation. The foundation is also a miniature signal foundation, being 8 inches square at the top, 17 inches deep and 11 inches square at the bottom, with four 3/4 inch hook bolts built into it.

The purpose of an indicator at the switch is to show to the person about to open it whether a train is approaching so near that the switch should not be opened, or whether the switch could be opened without interfering with the movement of trains. The construction of the indicator is shown by a sectional view in Fig. 19 and its assembly by Fig. 20, page 38.
The indicator consists simply of an electromagnet with coils, a, of 0.1 ohm resistance, and cores of 5/8 iron sheathed on the faces, b, of the iron yoke. The yoke, e, is clamped to the cores of the coil, a. The armature, c, is supported on the case, d, which is pivoted at its back on the terminal screws, f. The free end of a, projecting toward, carries the line connection, h, attached to the cramp, i, which is fixed to a shaft, j. This shaft carries the small metal blade, k, which is opposed to one end of the direction screws, i, and on the other end by the armature coil, e. When the armature, e, is attracted to the line faces by energizing coils, a, c, d, e, f, g, h, i, j, k, means of crank, i, causes the semicircular shaft, j, to rotate and with it the blade, k. The armature is at the end of its stroke, the blade, k, points downward the degrees, which is the clear or safety indication, while the position shown is the danger position.

The danger position of the indication is obtained by the action of gravity, as in the main signals. The magnet is supported by the circular disk, n, which covers the hole front of the case and is sealed tight. The binding posts, o, are the terminals of the coils to which the operating circuit is connected.

The front of the case is of glass, and the cover, l, is fitted into the back and seamed on at the edges with a black casing, m, operated by a leather gasket, n, screwing nut, o, which is the...
The hasp is locked in position by placing a latching block in the hasp. The wires are brought up through the latching block and attached to the binding posts. The circuits for the operation of the indicator will be pointed out later.

All wires, with the exception of the line wires, are protected by lacing them in grooved lumber or trim lining. Three sizes are used in order to fulfill specifications for use. The smallest is made by cutting a groove one inch for the line wire. The second size has a groove one half inch wide. The third size is made by cutting a groove one inch wide for the line wire. The second size is covered by a log of inch thick. The third size is the fifth of the trimming.

All lumber is placed on 5" x 4" oak stakes, four feet long, driven into the ground. The trimming is all painted before being installed. The assemblage point for wires crossing under tracks, the trimming is placed so that the top of the covering is at least one inch below the base of the rail.

All wires in signal cases, relay boxes, indicator cases, etc., are marked in block figures i.e., 3/16" X 17/16" long. In this tag is stamped the connection resulting from sending current through the wire to which it is attached. In addition to this, a number of the line wire to which it connects is written on the tag.
The line which is tied to the cross arm at the pin to which the line wire is tied. These numbers correspond to those on the line tags in the cases.

The semaphore blades are 4' 5" of long; 1' 10" and 1' 10" wide at the center end. They are made of the usual steel casting, six 1/4" carriage bolts. Two head stay bolts, on each side of a piece of metal 9 inches long, the center end. The front of the blade is painted yellow with a black stripe 3-5/". The center cross it fifteen inches from the center and is made to be painted black, with a similar stripe 15 inches in the same position.

The lamp used are the "B" Dressel Semaphore lamp. They are "cruciform" and are arranged with others in line to give eight positions as clearly indicated.

At Calumet Bridge, the line wire is taken across the river through a lead covered submarine cable laid on the bottom of the river. The track circuits are carried directly across the bridge. To do this, a special circuit controller is necessary, which will make connections in line with the rails on the face of the bridge. The difficulties met in the design of such an instrument are chiefly brought about in account of the general action of the Dressel lamp while a train is crossing over it. Motion in all directions must be allowed.
and from injuring the contact bars and their protective covering. Fig. 31, page 74, shows the bridge circuit controller assembled, and a brief explanation will suffice to make its operation clearly understood.

The case, a, Fig. 31, is fastened to the abutment timber. The guide, b, is fastened to the end tie on the span. The case, c, slides back and forth in guide, b, its movement toward the abutment case, a, being limited by the stop rib, d, striking the edge of the guide, b. Guides within case, c, the frame, e, slides. To this frame, the contact bars, f, of phosphor-bronze are connected by rivets, g. These contact bars, f, are guided at the end of case, c, where they slide through the hard wood block, h. Frame, e, is connected at rod, i, to the line running out from a lever in the interlocking tower. Case, a, contains the cast brass contacts, j, which are riveted at k and pressed together by the compression spring, l. The case, b, contains the phosphor-bronze contact brushes, m. Thus h is one end of the circuit and m is the other, the connection from one to the other being made through contact bars, f. If it is desired to disconnect the bridge circuit, the abutment, the lever in the tower is reversed, drawing frame, e, toward the rear end of case, c, and withdrawing contact bars, f, from contacts, g, thus breaking all circuits. At this point, the frame, e, strikes the rear end of case, c, and three inches of stroke still remain. Thus case, c, is moved and from
of a distance from it... which gives ample clearance for the bridge to turn. The lever's movement is evident. One of these controllers is used at each end of the draw span, there being a double track across the bridge; i.e., four rails; consequently, the four contacts.

For the protection of trains at interlocking plants, every precaution has been taken. Electric locks have been applied to the mechanical locking of the machine, which not only prevents the tower or from moving switches when a train is nearing his tower, but has also given it a clear signal, but also indicates to him that his signals are in their proper position by releasing the lock. Other indicators are used in the tower, which show to the towerman the condition of the track section through the interlocking plant. They also remind the towerman to return his lever to its normal position behind a leading train before he can again clear the same signal by reversing the lever. Screw releases, operated by hand, are also provided to release the electric locks, in case it becomes necessary to change routes with a train standing ahead of the signal. These require from ten seconds to a minute to operate, and the main purpose is to force the towerman to think of what he is doing before he can in any way endanger an approaching train.
The electric loco. used in this installation is shown in section in Fig. 23, a e f. 1. This is not only a lock but a circuit controller as well. The lock arm is attached to the armature of an electro-magnet similar to the switch indicator magnets, previously described. The coils, a, are carried by the magnet frame, e, which also acts as a pivot support for the lock arm, c. The short end of lever, e, is connected to the armature, d. The long end of the arm, c, extends to the end of the case, 7, where it is guided by lugs, 0, one on either side. Under these lugs, a circular cast iron disk, f, rotates on the shaft, g. This disk is notched out so that at a given point in its rotation the arm, c, will drop into this notch and lock the disk in that position. It is unlocked by energizing the coils, a, these cores attract the armature, d, lifting the long end of arm, c, upward out of the slot in disk, f, releasing it. In disk shaft, g, hard rubber sleeve, h, carries around its circumference contact strips of phosphor-bronze. These strips are of the same width as the contact brushes, i, and are entirely hidden by these in the figure. There are two rows of the brushes, i, and other row occupying a similar position behind sleeve, h, so that the circuits are controlled between a brush on the front side and a brush directly behind it on the rear side; the contact strips in the circumference of h closing or breaking this circuit, as h is rotated with disk, f.
The indicator, $j$, shows through glass covered openings, $k$, and is operated by the arm of the lock, thus indicating the position of the lock arm. The cover, $l$, is placed over the lock and secured by first passing it over stud, $m$, then locking by means of a takedown in base, $n$.

The disk, $f$, through which the locking is accomplished, is driven through an opening directly under it, by connection with the latch of the interlocking lever. The notch in it may be cut in any position desired. It may be arranged so as to lock when the lever is normal with latch lifted; with lever reversed, latch down; ith lever normal and latch down. In this installation, all notches are cut so as to lock the latch up, with lever normal. Fig. 23, page 75, is a mounted catalogue plate of the lock and its details, numbered for ordering.

There are three different types of interlocking machines in the eight interlocking plants embraced in this layout, i.e., six Saxby & Farmer machines, one National machine and one Standard machine. The manner of attaching the lock to the National and Standard machines is similar, but very different from that of attaching to the Saxby & Farmer machine. The attachment to the National machine is shown in Fig. 24, page 76, and to a Saxby & Farmer machine in Fig. 25, page 77. In the former, $\text{Fig. 25}$, to which the link driving the lock disk through $s$, $t$ and $u$, is connected, is driven up and down by the latch on the levers above. In Fig. 26, the shaft which drives the crank $h$, 
connected to the lock disk by the link, \textit{etc.}, Fig. 23, is rotated by the latch of the lever. This shaft also drives the mechanical locking of the machine. The lock to the left is shown in the locked position; while the lock to the right is shown in the position with lever reversed, and latch down.

The Tower Indicator is shown in Fig. 26, page 79. A is a side elevation with the case in section, and B is a front elevation with case in section. This indicator will be recognized as the standard relay, described previously, enclosed in an iron case, with a connection to its armature to operate the miniature signal blade which is placed behind a glass front, as in the case of the switch indicator. With the detailed description of the relay itself fresh in mind, Fig. 26 will explain itself.

The Hand Release, or more correctly termed Electrical Screw Release, is shown in Fig. 27, page 80. It consists simply of a speed reducing combination of a worm and worm wheel, which drives the contact strips, which connect a brush on one side with a brush on the other, completing a circuit. The whole, with the exception of the crank, is enclosed in an iron case and locked or sealed.

In Fig. 27, the crank, a, drives the worm, b, which in turn drives the worm wheel, c. In the worm wheel shaft, d, and driven by the worm wheel, is the crank stop, e, attached to c by screw, f, for driving purposes only. In the hub of e is fixed the hard rubber collar, g, which carries the contact strip, h. The brushes, i and j, slide
on the circumference of a hard rubber collar, and are connected through the strip, h, then its jaws to the stop position. They are mounted on the frame, h, and connections are made to them through binding posts, i and j. The contact strip, h, is so placed relative to e that it connects brushes, i and j, just as e strikes a stop on the frame as it rotates to the right.

On the but of wheel, c, on the opposite side are mounted a hard rubber collar and brushes, duplicates of collar, g, and brushes, i and j. Its contact strip is so arranged that it makes contact between the two brushes only when wheel, c, is rotated to the left until a stop lug on its side strikes a lug on the frame, thus the two extreme positions. When wheel, c, is rotated to the left as far as it will go, the circuit on the opposite side of the wheel is closed; but when wheel, c, is rotated to the right, this circuit is immediately broken, and, at the point where the rotation is stopped by the crank, e, the circuit is closed between i and j. The normal position is with wheel, c, rotated to the left as far as it will go, thus keeping circuit closed. The complete operation consists of starting at normal position, of rotating to right until stopped, then returning to normal. Holes are provided every 30 degrees for adjusting the stop, ar., e, so that by turning crank, d, as fast as possible by hand, a complete operation will require ten, twenty, thirty, forty, fifty and sixty seconds for the six different positions allotted.
The application of this electrical screw release will be pointed out in the discussion of the circuits following.

The different parts, their application and their duties have been thoroughly discussed in the preceding pages. All the important features of each, as adapted to a system, the sole purpose of which is safety, have been emphasized. The principles used in the wiring and circuits have been explained. In closing, a complete diagram of the circuits, showing local and line connections, is submitted in Fig. 20, page 85. These circuits were worked up and drawn in every detail by the author, to fulfill the terms of the contract and specifications as submitted by the Railroad Company. Only a few special explanations are considered necessary to enable the reader to trace out the different circuits in a satisfactory manner.

Attention is first directed to the table of conventions on the face page of the circuit diagram. These, with those already pointed out in the discussion of Figs. 4, 5 and 17, cover all conventions used in the diagram.

Instead of drawing the detail connections for each signal, as shown in Fig. 5, the 45 degree or caution position and 90 degree or clear position have been shown in diagramatic form and marked 45 and 90 respectively. All of the main operating batteries have been shown in duplicate sets, representing the storage battery and its charging set of gravity battery. The simple circuits for the straight automatic signals have been explained in Fig. 5, so that

these will be traced out on the line diagram with the greatest ease. In order that we come into line the Wise-Semaphore and the tower signals may be as clear, the circuits for automatic signal JSCS and semi-automatic signal JSL at State Street Interlocker, with their connections in the tower, will be taken up in detail.

Signal J4 stands normally at "caution", being a semi-automatic signal. Therefore, the automatic signal J3 will stand normally at "caution", as pointed out under Fig. 5. In the same manner, signal J4 stands in signal J3 for its clear position. The caution position is similar, considering its block unoccupied, is direct, under the control of the towerman; while its clear position is still indirectly under the towerman's control.

With the block in front of signal J4 unoccupied, the conditions necessary to place it in operation are as follows: Towerman must line the route governing signal J4 through the interlocking plant so that the lever will be released as controlled by the interlocking machine itself. Thus, derail A is closed, closing the circuit closer in the switch box, A, which closes the relay, B, to which, closely the third wire. This constitutes the actual derail circuit specified. The tower in this reversed lever, and, when its latch is unhooked and returned, closing the circuit closer, which is a part of the electric box as described, moves into the dotted position. The controlling circuit is connected, viz.: positive battery, B; wire, c; wire, h; front point, d, of relay, G; wire, e;
to an indication. 2. wire, 1; line w. controlled, 1. 2. 3. 4. 5. front points. 3, contact, 1; front points, 1, contact, 3; rear of relay, 7; wire, 2; disc, 9; positive battery, 1. 6. coils of relay, 1, are energized, exciting the circuit and closing the front points. 3. the 45 deg. circuit. viz.: positive battery, 1; line, c; front points, 1, of relay, 3; wire, 3; wire, 4; negative battery, 3. 7. This circuit operates the mechanism of signal 2 and pulls blade down to the 45 deg. position.

This movement of signal 4 moves the circuit controllers, which are the disks in the main shaft, to the position shown by the dotted line. Disks 1 closes the circuit, while disks 3 and 5 break circuits of this movement. The circuit closed by disk, 1 is as follows: positive battery, 1; wire, c; front contact, 1; motor, 1; line, disk, 1; wire, 1; line, the circuit, 1, wire, 2; coils of relay, 3; line, 2; line, 3; line, 4; line, 5; line, 6; wire, n; negative battery, 3. This circuit energizes coils, 1, closing its front points. This completes the circuit through the 90 deg. mechanism of signal 3 5, and its blade is pulled down to the clear position. With disk 3, its contact, 1. The locking circuit which provides protection for both the towerman and the engineer is contained as follows: positive battery, 3; wire, 22; wire, 20; contact 2; disc, 5, coil, 3; coil, 1;
wire, ff; line, lock; wire, f; ...wire, ii; line, lock 4 to signal 4; wire, g; contact, 2; wire, ii; line, lock 4 to signal 4; wire, ii; line point, i; wire, ii; line point, i; line, lock, 4 to signal 4; wire, ii; contact, 1; ...wire of lock, i; through wire, ee; contact, ...which is included in the electric lock, i; wire, ii; line, common; wire, ii; negative terminal, ss; at signal 205; following through this circuit, it is evident that in order to energize the coils of lock, i, the short track section in front of signal 205 must be unoccupied and the track section governing the caution position of signal 203 must be unoccupied and the track itself must be in some position between the horizontal and the caution position; also, on account of contact 2 of signal 2, the whole track section must be in a stop position and the latch on lever 4 controlling contact, ii, must be raised in full-reversed. From this, it is seen that if lever 4 in the track is reversed, operating signals 4 and 205 as described, it may be utilized to the normal position, returning signals 4 and 205 to their normal positions at any time. If no train has, in the meantime, passed into the short section in advance of signal 205, the locking circuit is completed if signals 4 and 205 do return to their normal position, at which, i, is energized, releasing the latch of lever 4 and allowing it to go down. However, if a train has passed into the advance section, the track relay of this section came, breaking the locking circuit and holding it on until the
end of this train has passed signal 4. The lever returns to its normal position at any time, returning signals 4 and 203 to their normal position, but the locking circuit is still held open by the train, and the latch in the normal position is locked up. It must be remembered that when the latch of a signal lever is up, all levers controlling switches and derails, overned to this signal are locked in the safe position.

For cases of emergency, the screw release circuit is provided, which will permit the releasing of the lock if the track sections named are occupied, after the lapse of from ten seconds to one minute. This time is required to take the screw release through one operation, as described above. This circuit is as follows: Positive battery, aa, at signal 2.5; wire, bb; wire, cc; contact, 3; wire, tt; line wire, ss, to signal 4; wire, mm; contact 3, uu; line wire, ss, to tower; wire, mm; wire, nm; front points yy, of stick relay; ss, ire, zz; front contact, nn, of screw release, uu; wire, mm; coils of lock, ll; wire, oo; contact, pp; ire, ll; line wire, mm; wire, rr; negative battery, ss.

A stick relay may be defined as one which, if the coils be energized from one circuit, closes, by means of one of its front points, another circuit, which will continue to energize its coils, although the first circuit be broken. Thus, the means provided in the screw release circuit for closing the front point, yy, is the reverse
contact, ab, of the screw release, ... Therefore, to pick up the stick relay, L, screw release, ..., is reversed, closing contact, ab, by breaking contact, ad, and the screw release circuit from line, av, passes through contact, ac; wire, ac; coils of relay, L; wire, ab; wire, bc; contact, ab; and back to common. This circuit picks up relay, L, and the holding circuit is made through line, ad; contact, ad; wire, ac; coils of relay, L; and so on, as before. It is evident, upon closing contact, ad, in order to close ab, that the main locking circuit was broken at ... Therefore, to pick up the lock, I, it is necessary to return screw release, ... to its normal position, closing contact, ... Quick relay, L, remains closed, however, as soon as contact, ad, is made, lock, I, is energized and the latch is released; circuit controlling L, returning from the dotted line position to the full line position, breaking the holding circuit of the stick relay L, holds open and will stay open until the next operation of the screw release. It is to be noted that this screw release circuit merely cuts around the track circuits. It is still necessary, in order to operate the screw release circuit, that the signals 4 and 5 be in their normal position.

The one other circuit connected with the control wiring is that of the tower indicator, which, according to specifications, must indicate the condition of the track section controlling the pole signal. If this were not done, the towerman must return his lever to the normal position.
after a train has passed the home signal, and then reversing
the lever before the signals will again operate. This is
accomplished by operating the tower indicator as a stick
relay, and the circuit is as follows: positive battery, b;
at signal c; wire, c; wire, h; front point d of relay; D;
wire, a; line wire, l.o.; wire, f; circuit control, a;
wire, ag; coils of indicator, I; wire, ah; wire, al; line
wire, common; wire, y; wire, n; negative battery, c. This
is the normal operating circuit of the tower indicator.
if the coils of indicator, m, are energized, its holding
circuit is completed through its front contact, ah; its
coils; and wire, ah; returning to battery over the same
wires as its operating circuit. Thus, then contact, a,
is shifted to the dotted position, which is the case when
the lever is reversed to clear the signal 4, the tower
indicator is held clear as a stick relay. However, then
track relay, D, is opened by the passage of the train,
front point, a, is broken, opening this holding circuit,
and the indicator indicates danger. It is now evident
that contact, a, must be returned to its full line position.
which is possible when the lever is normal, latch down;
and front point, a, of relay, D, must be closed before in-
dicator will again be energized. This means that the track
section to which relay, D, is connected, must be unoccupied.
The wiring, as traced out above, is practically the same
at all interlocking plants.
At the Burnside Interlocking limit, it is noted that the Calumet Electric Street Railway crosses the Chicago & Western Indiana track inside the interlocking limits. In order that the track battery may feed both directions thru this point, it was necessary to make two track sections between signals 213 and 214 on the southbound track, and between 215 and 216 on the northbound track. The slight change in circuits necessitated by this arrangement is easily traced out.

At Pullman Junction, the first switch indicator circuit is encountered. It will be noted that this circuit is merely turned off from the tower indicator circuit by means of a circuit closer on the electric list. It, therefore, operates the same as the tower indicator with the exception that when the latch of lever 214 is lifted, the switch indicator circuit is broken and it indicates danger. It remains in this position until the train has passed signal 213, southbound.

Just south of Pullman Junction, the tracks are again crossed by the Calumet Electric Street Railway, and the track battery feeds in both directions thru this crossing.

It has been pointed out that signals 210 and 211, 213 and 214, and 217 and 218 are placed upon one same pole, commonly known as the bracket pole. A working drawing of this bracket pole is shown on page 81, Fig. 29, which will make its construction plain. This same bracket pole is used at signal 19, with one case removed.
At 112th Street, the second switch indicator circuit is shown, in connection with the interlocking plant. It is practically the same as the switch indicator at Pullman Junction and its circuit will be understood without difficulty. The next switch indicator is located just south of 112th Street, on the southbound track, and its connections are identical with that at Pullman Junction. Two more switch indicators are located on the northbound track at Burnham. Their location relative to the interlocking plant necessitates the same sort of arrangement in their circuits.

At State Line interlocking plant, it should be noted that signal 233 operates in connection with the semi-automatic signal 162 and the mechanically operated signal 158; that is, signals 162 and 158 must be in the clear position in order to clear signal 233. Signal 158 is operated mechanically from the interlocking tower. The circuit closers shown in connection with it are the same as the mechanically operated signal at Hammond Junction, and an assembled drawing, which will be easily understood, is shown in Fig. 30, page 33.

In this brief explanation of the circuits presented in the circuit diagram of Fig. 23, the writer desires only to assist those who may have the patience and interest to trace out the circuits to their own satisfaction, to take a start in the right direction.
